Abstract

Objective: To investigate whether post-ischemic administration of minocycline attenuates hind-limb motor dysfunction and gray and white matter injury after spinal cord ischemia.

Design: A prospective, randomized laboratory investigation

Setting: Laboratory in university, single-institutional

Participants: Male New Zealand White rabbits

Intervention: Spinal cord ischemia was induced by an occlusion of infrarenal aorta for 15 min. Group M1 (n=8) with a minocycline administration 1 hour after reperfusion; Group M3 (n=8) with a minocycline administration 3 hours after reperfusion; Group C (n=8) with a saline administration 1 hour after reperfusion or Sham group (n=4). Minocycline was intravenously administered at 10 mg/kg a total of 6 times at 12-hour intervals until 60 hours after the initial administration.

Measurement and Main results: Hind limb motor function was assessed using Tarlov score. For histological assessments, gray and white matter injury was evaluated 72 hours after reperfusion using the number of normal neurons and percentage areas of vacuolations, respectively. The motor function 72 hours after reperfusion was significantly better in the

Group M1 than in the Group C. The number of neurons in the anterior horn was significantly higher in the Group M1 than in the Group M3 or C, but did not significantly differ between Groups M3 and C. No significant difference was noted in the percentage areas of vacuolations among the ischemia groups.

Conclusions: Minocycline administration beginning at 1hour after reperfusion improved hind-limb motor dysfunction and attenuated gray matter injury in a rabbit spinal cord ischemia model.

Introduction

An important complication of thoracic or thoracoabdominal aortic aneurysm is lower limb paralysis due to spinal cord ischemia (SCI) (1, 2) . Hypothermia therapy, spinal cord drainage, and various drug therapies to protect the spinal cord from ischemia have been reported (3, 4), but their effects are limited. Therefore, further efforts to clarify the mechanisms of nerve injury and develop neuroprotective drugs are being made.

Minocycline is a semi-synthetic tetracycline antibiotic that passes the blood-brain barrier and enters the central nervous system, and is noted for its biological other than antibiotic actions (5-8). It has been reported to reduce the size of ischemic foci using brain ischemia models (9-12). On the basis of these reports, an open-label trial was conducted in acute stroke patients, showing a more favorable outcome compared with the placebo group (13). In spinal cord injury models, minocycline has been shown to alleviate the impairment of spinal cord tissue and improve motor functions in contusion and compression models (14-17).

Our previous study indicated that intraperitoneal administration of minocycline before

ischemia improved the hind limb motor function and alleviated impairment of the gray and white matter in a rat SCI model (18). However, there are no data available on minocycline-mediated neuroprotection when administered after reperfusion in a model of SCI. The present study was conducted to examine whether minocycline administration after reperfusion also has a neuroprotective effect in a rabbit model of SCI, and evaluated the therapeutic window period of this effect.

8 **Methods**
9

10
11 This study was approved by the Animal Experiment Committee of Nara Medical University
12
13 (Kashihara, Nara, Japan). Twenty-eight New Zealand White rabbits weighing 2.7-3.0 kg were
14
15
16
17 used. These rabbits were housed under 12-hour light-dark cycles with free access to food and
18
19
20
21 water.
22
23
24
25
26

27
28 *Animal allocation*
29
30

31 The rabbits were randomly allocated to one of the following 4 groups: Control (C) group
32
33 (n=8), minocycline administration after 1 hour (M-1) group (n=8), minocycline
34
35
36 administration after 3 hours (M-3) group (n=8), or sham group (n=4). In the M-1 and C
37
38
39
40 groups, minocycline (Nichi-iko, Toyama, Japan) or normal saline was administered
41
42
43
44 intravenously every 12 hours from 1 hour after reperfusion for 60 hours (a total of 6 times). In
45
46
47 the M-3 group, minocycline was also administered every 12 hours for 60 hours, but the
48
49
50 administration was started 3 hours after reperfusion. The dose of minocycline was 10 mg/kg
51
52
53
54 (in 3 ml). The sham group was administered the same amount of normal saline employing the
55
56
57
58 same schedule as in the C group without aortic occlusion.

Spinal cord ischemia

The rabbits were anesthetized in a plastic box using oxygen and 5% isoflurane. A catheter was inserted into the auricular vein, and Ringer's solution was administered at 10 ml/kg/h. The auricular artery was cannulated, and the proximal arterial pressure was measured. After the intravenous administration of fentanyl at 50 µg/kg, endotracheal intubation was carried out, and artificial ventilation (Harvard Respirator 510: Summit Medical, MA) was performed using 2-3.5% isoflurane, 30% oxygen, and air by adjusting the end-tidal carbon dioxide pressure to 35-40 mmHg. The rectal temperature was monitored continuously, and it was adjusted to 38-39°C using an electric mat. For measurement of the distal arterial pressure and blood sampling (blood gas and blood sugar analyses), the right femoral artery was exposed, and an SP-55 catheter was inserted. A 50-mm flank incision at the left costal level was made after infiltration of 1% lidocaine, and the aorta was exposed from the retroperitoneal cavity at the left renal artery level. A silicone thread 1.5 mm wide was carefully placed around the aorta immediately distal to the left renal artery, and both ends of the thread were passed through an occluder tube. Prior to the induction of ischemia, 600 U of heparin was administered. The

1
2
3
4
5
6
7
8 aorta was occluded by tightening the thread using the tube, and occlusion was confirmed by
9
10 monitoring the distal pressure. After 15 minutes, aortic occlusion was released. After
11
12 reperfusion, all catheters were removed, and the wound was closed. Blood was sampled 10
13
14 minutes before aortic occlusion and 10 minutes after reperfusion. The blood pressure and
15
16
17 minutes before aortic occlusion and 10 minutes after reperfusion. The blood pressure and
18
19
20 body temperature were measured 10 minutes before aortic occlusion, during the ischemia (7.5
21
22
23 minutes after aortic occlusion), and 10 minutes after reperfusion.
24
25
26
27
28
29
30

31 *Neurological evaluation*

32
33
34 The hind limbs of the rabbits were neurologically evaluated 24, 48 and 72 hours after
35
36
37 reperfusion by a blinded observer. Assessment was made using Tarlov scoring (19), which
38
39
40 consists of a five-point grading scale : 0 = paraplegic with no lower extremity function; 1 =
41
42
43 poor lower extremity function, weak antigravity movement only; 2 = some lower extremity
44
45
46 motor function with good antigravity strength but inability to draw leg under the body or hop;
47
48
49
50
51 3 = ability to draw legs under the body and hop but not normally; 4 = normal motor function.
52
53
54
55
56
57

58 *Histological evaluation*

1
2
3
4
5
6
7
8 Following the neurological evaluation after 72 hours, 50 mg/kg of thiopental was
9
10 administered intraperitoneally, and the animals were anesthetized deeply using 5% isoflurane.

11
12
13 After 1,000 ml of cold heparinized physiologic saline was infused transcardially, 500 ml of
14
15 4% paraformaldehyde in 0.1M PBS was administered. The lumbar spinal cord was removed,
16
17
18 immersed in paraformaldehyde for 2days, the L5 part was cut off, embedded in paraffin, and
19
20
21
22
23
24
25 sliced at a thickness of 3 μm for hematoxylin and eosin staining.
26
27
28
29
30

31 Gray matter injury was evaluated in terms of the number of normal neurons remaining in the
32
33
34 left anterior horn of the spinal cord. An observer not informed of the randomization results
35
36
37 counted normal neurons in an area of the left hemisphere anterior to the central canal of the
38
39
40
41 spinal cord under light microscopy ($\times 200$). White matter injury was evaluated by examining
42
43
44 the ventral, ventrolateral, and lateral areas and calculating the percentage areas of vacuolation,
45
46
47 comprising the percentage of a 0.04-mm^2 area occupied by vacuoles. Each area was divided
48
49
50
51 into 144 sub-areas using grid lines, a sub-area was regarded as a vacuolated area if 75% or
52
53
54 more of it was occupied by vacuoles, and the percentage of vacuolated sub-areas in the 144
55
56
57
58 sub-areas was calculated. The total percentage of areas of vacuolation was calculated as a

mean of the 3 areas on each side.

Statistical analysis

The physiologic variables, number of normal neurons, and percentage areas of vacuolation were analyzed employing one-factor analysis of variance, and Fisher's PLSD was used as a post-hoc test. The motor function of the hind limbs was examined with the Kruskal-Wallis test, and the Mann-Whitney U-test was used as a post-hoc test. P value less than 0.05 was considered significant.

6
7
8 **Results**
9

10
11 Physiological variables are shown in table 1. There were no significant differences in the body
12
13 weight or rectal temperature among the groups. Blood pressure values were similar among the
14
15 groups before aortic occlusion, however, were significantly higher in the sham group than the
16
17 ischemic groups during ischemia. Blood gas data are shown in table 2. No significant
18
19 difference was noted in any of the blood test items including the pH, PaCO₂, PaO₂, hematocrit,
20
21 and blood glucose level among the groups.

30

31
32
33
34 Tarlov Scores 24, 48 and 72 hours after reperfusion were shown in table 3. Figure 1 shows the
35
36 individual neurologic scores 72 hours after reperfusion. Tarlov Scores in the sham group were
37
38 significantly higher compared with those in the 3 groups exposed to ischemia. Tarlov Scores
39
40 72 hours after reperfusion were significantly higher in the M-1 group compared with those in
41
42 the control group. No significant differences in Tarlov Score were noted between the C and
43
44
45
46
47
48
49
50
51 M-3 groups.

hematoxyline and eosin-stained section were shown in figure 1 and 2, respectively. The numbers of normal neurons were shown in figure 3. The number of normal neurons was significantly higher in the sham group than those in the other 3 groups. The number of normal neurons in the M-1 group was significantly higher than those in the control group. There were no significant differences in the number of normal neurons between the C and M-3 groups. Figure 4 shows the total percentage areas of vacuolation in each group . Percentage areas of vacuolation in the C group were significantly higher than in the sham group. While no significant differences were noted among the 3 groups exposed to ischemia, the percentage areas of vacuolation were lower in the M-1 group than in the C group.

3
4
5
6
7
8 **Discussion**
9

10
11 The results in the present study showed that intravenous administration of minocycline for 3
12
13
14 days at an interval of 12 hours, beginning at 1 hour, but not 3 hours, after reperfusion,
15
16
17
18 significantly improved the hind limb motor function and significantly increased the number of
19
20
21 normal neurons in the anterior horn 72 hours after reperfusion in rabbits subjected to spinal
22
23
24 cord ischemia for 15 min, while the percentage areas of vacuolation were not affected by the
25
26
27 administration of minocycline. These results suggest that minocycline administration after
28
29
30 reperfusion can be neuroprotective, but early initiation of administration would be necessary
31
32
33
34 for the treatment to be effective.
35
36
37
38
39
40

41 Although there has been no data available regarding the post-ischemic administration of
42
43
44 minocycline in a model of spinal cord ischemia, neuroprotective effects of minocycline have
45
46
47
48 been shown in models of cerebral ischemia (9-11, 20). Yrjänheikki et al. (9) reported that
49
50
51 intraperitoneal administration of minocycline, beginning at 12 hours before ischemia or 30
52
53
54 minutes after reperfusion increased the number of remaining CA1 pyramidal neurons in a rat
55
56
57
58 model of global cerebral ischemia. They also reported that monocycline administration,
59
60
61
62
63
64
65

1
2
3
4
5
6
7
8 beginning at 12 hours before ischemia or 4 hours after reperfusion significantly decreased the
9
10
11 infarct volume after middle cerebral artery occlusion in rats (10).
12
13
14
15
16

17
18 Regarding the effects of minocycline on SCI, our previous report (18) in a rat aortic occlusion
19
20
21 model is the first to our knowledge. We administered minocycline intraperitoneally at 45
22
23
24 mg/kg at an interval of 12 hours before ischemia, and reported the alleviation of impairment
25
26
27 of the hind limb motor function and white and gray matter injury after 72 hours. The results in
28
29
30 the present study indicated a neuroprotective effect of minocycline, which was administered 1
31
32
33
34 hrs, but not 3 hrs, after reperfusion in a rabbit model of SCI.
35
36
37
38
39
40

41 In the present study, a rabbit model of SCI was used due to the following reasons. First, in a
42
43
44 rat SCI model, it has been reported that motor function gradually improved without no
45
46
47 delayed deterioration, while hind-limb motor function deteriorated after SCI over 2 weeks in a
48
49
50 rabbit model (21). Delayed development of paraplegia is well known in human, so that the
51
52
53
54 time course after SCI in human may resemble to that in rabbit. Second, peritoneal
55
56
57
58 administration is not appropriate for further clinical application and for accurate assessment of
59
60
61
62
63
64
65

1
2
3
4
5
6
7
8 therapeutic window due to variation in the absorption rate (5, 8). Repetitive intravenous
9
10
11 administration could be performed if a rabbit model was used.
12
13
14
15
16

17
18 The dosage of minocycline in the present study was determined in the following reasons. The
19
20
21 blood level of minocycline is considered to be similar after intravenous administration at 20
22
23
24 mg/kg and intraperitoneal administration at 90 mg/kg in rats (8). Xu L et al. (11) reported that
25
26
27 the blood minocycline level on intravenous administration at 3 mg/kg in rats was equal to that
28
29
30
31 at 200 mg in humans, which is a standard dose for humans. In the present study, we set the
32
33
34 dose for intravenous administration at 10 mg/kg every 12 hours on the basis of the dose used
35
36
37 in rabbits in expectation of an antibiotic effect (6 mg/kg, i.v., every 8 hours) (22). As a result,
38
39
40
41 intravenous administration of minocycline at this dosage for 3 days at an interval of 12 hours,
42
43
44 beginning at 1 hour, but not 3 hours, after reperfusion, significantly improved neurological
45
46
47 outcome and alleviated gray matter injury 72 hours after reperfusion.
48
49
50
51
52
53

54
55 Although exact mechanisms of minocycline-mediated neuroprotective effects in this study are
56
57
58 unknown, possible mechanisms may include anti-inflammatory actions due to the suppression
59
60
61
62
63
64
65

1
2
3
4
5
6
7
8 of microglia activation and subsequently decreasing the release of cytokines and chemokines
9
10
11 (10,15,23-25), anti-apoptotic actions (26,27) due to inhibition of cytochrome C release(17)
12
13
14 and caspase expression (28,29), inhibition of proNGF (Nerve growth factor) production (30),
15
16
17 prevention of toxicity of glutamic acid (10), suppression of NO synthetase (22), and
18
19
20
21 inhibitions of p38MAPK activation in microglia (22, 25, 30). However, since we did not
22
23
24 perform the study to clarify the mechanisms of minocycline-mediated neuroprotection, further
25
26
27 studies would be required.
28
29
30
31
32
33

34 There are several limitations in this study. First, concerning the dose, minocycline might also
35
36
37 have been effective in the M-3 group if it had been administered at a higher dose or different
38
39
40 regime for administration. Second, concerning the severity of ischemia, the results may have
41
42
43 changed depending on the severity of SCI. However, the data of our previous studies
44
45
46 indicated that 13-15 minutes time of ischemia is appropriate to evaluate the effect of
47
48
49 neuroprotection. Aortic clamping for more than 20 minutes is too severe to destroy the spinal
50
51
52 cord tissue. Third, the group in which minocycline was administered before ischemia, was not
53
54
55 included in this study. So it is unclear whether administration of minocycline before ischemia
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6
7
8 is more effective than that after reperfusion. Fourth, regarding the white matter injury, the
9
10
11 evaluation at more than 4 days but not 72 hours after reperfusion might be appropriate. Kurita
12
13
14 et al. (21) reported that white matter injury was unclear 24 hours after reperfusion but became
15
16
17 clear after 4 days in a rabbit SCI model. Fifth, demonstration of neuroprotection in animal
18
19
20 species does not necessarily translate to humans. Finally, concerning the long-term outcome,
21
22
23
24 evaluation of the motor function and histological changes after a long-term interval after
25
26
27 reperfusion would be necessary.
28
29
30
31
32
33

34 In summary, the effects of the intravenous administration of minocycline on white and gray
35
36
37 matter injury and motor function were evaluated in a rabbit 15-min SCI model. As a result, an
38
39
40 improvement in the motor function and alleviation of gray matter injury were observed after
41
42
43
44 72 hours when the drug was administered 1 hour after ischemia, but not when it was
45
46
47 administered after 3 hours. Since minocycline is widely used clinically as an antibiotic,
48
49
50 sufficient evaluation of its use as a drug for the prevention of paraplegia associated with
51
52
53
54 surgery for thoracoabdominal aortic aneurysm is justified. While further evaluation would be
55
56
57 necessary concerning its safe and effective use, its administration early after the onset of

Figure legends

Figure 1

Histograms of the Tarlov score after 72 hours and the numbers of neurons per animal in the sham, control (C), minocycline administration after 1 hour (M-1), and minocycline administration after 3 hours (M-3) groups.

Figure 2

Representative photomicrographs of hematoxylin and eosin-stained section in the anterior horn of the spinal cord in the sham (a), the control (b), the M-1 (c), and the M-3 (d) groups. Normal neurons were better preserved in the M-1 group compare with those in the control and the M-3 groups.

Figure 3

The numbers of normal neurons in the sham, control (C), minocycline administration after 1 hour (M-1), and minocycline administration after 3 hours (M-3) groups. Of the 3

groups exposed to ischemia, the number of remaining neurons was higher in the M-1 group than in the other 2 groups ($p < 0.05$).

Figure 4

The total percentage areas of vacuolation in the sham, control (C), minocycline administration after 1 hour (M-1), and minocycline administration after 3 hours (M-3) groups. It was significantly higher only in the C group than in the sham group ($P < 0.05$). No significant difference was noted among the 3 groups exposed to ischemia.

Table 1. Physiological variables

	Sham (n=4)	C (n=8)	M-1 (n=8)	M-3 (n=8)
Weight (kg)	2.9±0.1	2.8±0.1	2.8±0.1	2.9±0.1
Mean arterial pressure (mmHg)				
Before	67±7	63±5	60±11	65±7
During	66±10	12±2 a	12±1 a	12±1 a
After	ND	54±10	52±7	57±4
Rectal temperature (°C)				
Before	38.7±0.2	38.6±0.4	38.5±0.3	38.6±0.3
During	38.3±0.3	38.7±0.3	38.5±0.2	38.7±0.3
After	38.4±0.4	38.6±0.3	38.7±0.3	38.5±0.2

Data are expressed as mean±SD. ND; no data.

Mean arterial pressure and rectal temperature were measured 10 minutes before aortic occlusion (before), during ischemia (7.5 minutes after aortic occlusion) (during) and 10 minutes after reperfusion (after).

a; P<0.05 vs. Sham.

Table 2. Blood gas data

	Sham (n=4)	C (n=8)	M-1 (n=8)	M-3 (n=8)
pH				
Before	7.49±0.04	7.46±0.05	7.50±0.07	7.4±0.05
After	7.46±0.01	7.44±0.06	7.45±0.05	7.4±0.04
PaCO ₂ (mmHg)				
Before	37±4	38±3	36±3	37±4
After	30±3	36±6	35±4	35±3
PaO ₂ (mmHg)				
Before	160±44	159±31	154±30	134±30
After	195±16	171±33	164±28	152±23
Hematocrit (%)				
Before	36±4	34±2	35±3	37±3
After	33±3	33±2	33±2	35±3
Glucose (mg/dl)				
Before	116±22	123±18	137±28	138±23
After	151±19	160±45	139±44	142±32

Data are expressed as mean ± SD. Blood gas data. Blood was sampled 10 minutes before aortic occlusion (before) and 10 minutes after reperfusion (after). There were no significant differences among the groups. PaCO₂ and PaO₂; arterial partial pressure of carbon dioxide and oxygen, respectively.

Table 3. Neurological outcome

	Tarlov score			
	Sham (n=4)	C (n=8)	M-1 (n=8)	M-3 (n=8)
24 hrs	4 (4-4)	2.5 a (2-3)	3 a (3-3.25)	2 a (2-2)
48hrs	4 (4-4)	2 a (2-2)	3 a (2-3)	2 a (2-2)
72hrs	4 (4-4)	2 a (2-2)	3 a,b (2-3)	2 a (2-2)

Data are expressed as median (25th-75th). a; P<0.05 vs. Sham, b; P<0.05 vs. C.

Tarlov score: 0 = paraplegic with no lower extremity function; 1 = poor lower extremity function, weak antigravity movement only; 2 = some lower extremity motor function with good antigravity strength but inability to draw leg under the body or hop; 3 = ability to draw legs under the body and hop but not normally; 4 = normal motor function.
